TAILORING GATE WORK-FUNCTION IN IMAGE SENSORS

FIELD OF THE INVENTION

[0001] The present invention relates to the field of semiconductor devices, particularly to an improved pixel cell for high efficiency charge transfer and reduced lag.

BACKGROUND OF THE INVENTION

[0002] Complimentary metal oxide semiconductor (CMOS) image sensors are increasingly being used as low cost imaging devices. A CMOS image sensor circuit includes a focal plane array of pixel cells. Each one of the cells includes a photo-conversion device, such as a photogate, photoconductor, or photodiode, overlying a charge accumulation region within a substrate for accumulating photo-generated charge. Each pixel cell may include a transistor for transferring charge from the charge accumulation region to a sensing node, and a transistor, for resetting the sensing node to a predetermined charge level prior to charge transference. The pixel cell may also include a source follower transistor for receiving and amplifying charge from the sensing node and an access transistor for controlling the readout of the cell contents from the source follower transistor.

[0003] In a CMOS image sensor, the active elements of a pixel cell perform the necessary functions of: (1) photon to charge conversion; (2) accumulation of photo-generated charge; (3) transfer of charge to the sensing node accompanied by charge amplification; (4) resetting the sensing node to a known state before a transfer of charge to it; (5) selection of a pixel for readout; and (6) output and amplification of a signal representing pixel charge from the sensing node. Photo-generated charge may be amplified when it moves from the initial charge accumulation region to the floating diffusion node. The charge at the sensing node is typically converted to a pixel output voltage by a source follower output transistor.

[0004] CMOS image sensors of the type discussed above are generally known and are discussed in Nixon et al., "256x256 CMOS Active Pixel Sensor Camera-on-a-Chip," IEEE Journal of Solid-State Circuits, Vol. 31(12), pp. 2046-2050 (1996); and Mendis et al., "CMOS Active Pixel Image Sensors," IEEE Transactions on Electron Devices, Vol. 41(3), pp. 452-453 (1994). See also U.S. Patent Nos. 6,177,333 and 6,204,524, which describe operation of conventional CMOS image sensors, the contents of which are incorporated herein by reference.

[0005] A schematic top view of a portion of a semiconductor wafer fragment containing a conventional CMOS pixel cell is shown in FIG. 1. The CMOS pixel cell 10 is a four transistor (4T) cell. The pixel cell 10 generally comprises a photo-conversion device 21 for collecting charges generated by light incident on the pixel, and a transfer gate 7 for transferring photoelectric charges from the photo-conversion device 21 to a sensing node 4, typically a floating diffusion region 4. The floating diffusion region 4 is electrically connected to the gate of an output source follower transistor 11. The pixel cell 10 also includes a reset transistor 9 for resetting the floating diffusion region 4 to a predetermined voltage before a photoelectric charges are transferred; a source follower transistor 11 which receives at its gate an electrical signal representative of the photoelectric charges from the floating diffusion region 4; and a row select transistor 13 for outputting a signal from the source follower transistor 11 to an output terminal in response to an address signal.

[0006] FIG. 2 is a diagrammatic side sectional view of the pixel cell 10 of FIG. 1 taken along line 2-2'. As shown in FIG. 2, in the conventional CMOS pixel cell 10 the photo-conversion device 21 is a pinned photodiode. The pinned photodiode 21 has a photosensitive p-n-p junction region comprising a p-type surface layer 5 and an n-type photodiode region 14 within a p-type active layer 1, which is typically a lightly doped p- active area. Adjacent to the pinned photodiode 21 is a gate 7 of a transfer transistor. Typically, the transfer gate 7 is

an n+ gate having a gate electrode 8 comprising a layer of heavily doped n-type polysilicon.

[0007] In the conventional CMOS pixel cell 10 depicted in FIGS. 1 and 2, charge in the form of electrons is generated by light incident externally to the pixel cell 10 and stored in the n-type photodiode region 14. This charge is transferred to the floating diffusion region 4 by the gate 7 of the transfer transistor. The source follower transistor 11 produces an output signal from the transferred charges. The output signal is proportional to the charge, or number of electrons, extracted from the n-type photodiode region 14.

[0008] Optimizing the characteristics of a transfer gate device is critical to providing a high performance CMOS image sensor. Ideally, a transfer gate should have very low leakage in the off state, a low threshold voltage, and no potential barriers that impede the flow of electrons in a region 30 where a photo-conversion device, such as the pinned photodiode 21, and transfer gate are in close proximity to one another. These characteristics can often conflict with one another and optimizing them is difficult.

[0009] In a conventional CMOS pixel cell having a photo-conversion device, such as pinned photodiode 21, a potential barrier might exist where the transfer gate 7 and pinned photodiode 21 are in close proximity: the photodiode/transfer gate region 30. FIG. 3 is a graph representing the potential (V) in the pixel cell 10 along the distance (D) of line 3-3' (FIG. 2) in a direction from the pinned photodiode 21 to the transfer gate 7 and the floating diffusion region 4 of the CMOS pixel cell 10. The potential profile of FIG. 3 shows the potentials that an electron may encounter, including a potential barrier 31, as it is transferred from the pinned photodiode 21 to the floating diffusion region 4.

[0010] As shown in FIG. 3, there is a potential barrier 31 corresponding to the photodiode/transfer gate region 30. If this potential barrier is too high, a portion of the charge will be unable to move from the

photodiode 21 to the floating diffusion region 4. The greater the potential barrier, the less charge will be transferred to the floating diffusion region 4. This potential barrier is influenced by the characteristics of the pixel cell 10, including: 1) p-type dopant levels in the channel region of the transfer gate 7; 2) dopant levels in the transfer gate 7 channel region used to adjust the threshold voltage; 3) transfer gate 7 oxide thickness; 4) pinned photodiode 21 surface p-type dopant levels; 5) pinned photodiode 21 n-type dopant levels; and 6) any background p-type dopant concentration.

[0011] The existence of a potential barrier in the photodiode/transfer gate region 30 is a significant problem in CMOS image sensors. A potential barrier in the photodiode/transfer gate region 30 causes incomplete charge transfer reducing the charge transfer efficiency of the pixel cell 10. Further, charge remaining in the photodiode 21 can affect charge collected for a subsequent image causing image lag, where a ghost image from the initial charge is apparent in a subsequent image. Previous methods to reduce this potential barrier have resulted in degraded sub-threshold leakage current for the transfer gate 7. It is difficult to optimize both the potential barrier and sub-threshold leakage current for the transfer gate 7 in CMOS image sensors. Accordingly, what is desired is a technique for manufacturing a CMOS pixel cell having both a reduced potential barrier in an area where a photodiode and a transfer gate structure are in close proximity to one another and also with low sub-threshold leakage characteristics.

BRIEF SUMMARY OF THE INVENTION

[0012] Embodiments of the invention address the problems described above and provide a method of forming a pixel cell and the resultant pixel cell. A pixel cell comprises a photo-conversion device formed at a surface of a substrate and a transistor adjacent to the photo-conversion device. The transistor comprises a gate overlying a channel region. The gate comprises at least one gate region having a work-function greater than a work-function of n+

polysilicon. The channel region comprises respective portions below each gate region. A dopant concentration in at least one portion of the channel region is determined at least in part by the work-function of the respective gate region. Tailoring the gate work-function using an alternative material and/or dopant characteristics for the at least one gate region allow the gate and its operation to be modulated and optimized. Specifically, a desired threshold voltage may be achieved with reduced or omitted channel doping, thereby helping both to reduce a potential barrier in region where a photodiode and transfer gate are in close proximity to one another and to provide superior sub-threshold leakage characteristics for the gate.

BRIEF DESCRIPTION OF THE DRAWINGS

[0013] The foregoing and other aspects of the invention will be better understood from the following detailed description of the invention, which is provided in connection with the accompanying drawings, in which:

[0014] FIG. 1 is a top plan view of a conventional CMOS pixel cell;

[0015] FIG. 2 is a diagrammatic side sectional view of the FIG. 1 pixel cell taken along line 2-2’;

[0016] FIG. 3 is a graph representing the potential profile of the FIG. 2 pixel cell along a cut-line 3-3’;

[0017] FIG. 4 is a diagrammatic side sectional view of a pixel cell according to an exemplary embodiment of the invention;

[0018] FIG. 5A depicts the FIG. 4 pixel cell at an initial stage of processing;

[0019] FIG. 5B depicts the FIG. 4 pixel cell at an intermediate stage of processing;

[0020] FIG. 5C depicts the FIG. 4 pixel cell at an intermediate stage of processing;

[0021] FIG. 6A is a top plan view of a portion of a pixel cell according to an embodiment of the invention;

[0022] FIG. 6B depicts a cross sectional view of the pixel cell of FIG. 6A along line 6B-6B';

[0023] FIG. 7A is a top plan view of a portion of a pixel cell according to an embodiment of the invention;

[0024] FIG. 7B depicts a cross sectional view of the pixel cell of FIG. 7A along line 7B-7B';

[0025] FIG. 8 is a schematic diagram of a pixel cell according to an embodiment of the invention;

[0026] FIG. 9 is a simplified block diagram of an image sensor incorporating the pixel cell of FIG. 6; and

[0027] FIG. 10 illustrates a simplified block diagram of a computer processor system incorporating the FIG. 9 image sensor.

DETAILED DESCRIPTION OF THE INVENTION

[0028] In the following detailed description, reference is made to the accompanying drawings, which form a part hereof and illustrate specific embodiments in which the invention may be practiced. In the drawings, like reference numerals describe substantially similar components throughout the several views. These embodiments are described in sufficient detail to enable those skilled in the art to practice the invention, and it is to be understood that other embodiments may be utilized, and that structural, logical and electrical

changes may be made without departing from the spirit and scope of the present invention.

[0029] The terms “wafer” and “substrate” are to be understood as including silicon, silicon-on-insulator (SOI), or silicon-on-sapphire (SOS) technology, doped and undoped semiconductors, epitaxial layers of silicon supported by a base semiconductor foundation, and other semiconductor structures. Furthermore, when reference is made to a “wafer” or “substrate” in the following description, previous process steps may have been utilized to form regions or junctions in the base semiconductor structure or foundation. In addition, the semiconductor need not be silicon-based, but could be based on silicon-germanium, germanium, or gallium-arsenide.

[0030] The term “pixel” refers to a picture element unit cell containing a photo-conversion device and transistors for converting electromagnetic radiation to an electrical signal. For purposes of illustration, a representative pixel is illustrated in the figures and description herein, and typically fabrication of all pixels in an image sensor will proceed simultaneously in a similar fashion.

[0031] Embodiments of the invention provide a method of forming a pixel cell for an image sensor and the resultant device. The pixel cell includes a photo-conversion device adjacent to a gate of a transfer transistor, which comprises a gate electrode. According to embodiments of the invention, the work-function of the transfer gate is tailored such that at a given threshold voltage, V_{t} , the dopant concentration in a channel region of the transfer gate is reduced or eliminated as compared to a conventional pixel cell 10 (FIGS. 1 and 2). Additionally, embodiments of the invention provide a transfer gate having a gate electrode comprising a plurality of regions having differently tailored work-functions.

[0032] The terms of the threshold voltage (V_t) equation include: the Fermi potential ($2\Phi_F$), the bulk charge (Q_B), the oxide charge (Q_{ox}), the normalized gate dielectric capacitance (C_{ox}), and the work-function difference (Φ_{MS}). The equation for V_t can be written as follows:

$$V_t = +|2\Phi_F| + |Q_B/C_{ox}| - |Q_{ox}/C_{ox}| + \Phi_{MS}$$

[0033] The Fermi potential ($2\Phi_F$) is dependent on channel doping and increases with increased doping. The bulk charge (Q_B) behaves the same way, but in a square root relationship. C_{ox} is the normalized gate dielectric capacitance and increases as the gate dielectric thickness is reduced. The oxide charge (Q_{ox}) is a function of gate dielectric processing and includes a fixed and interface charge. The work-function difference (Φ_{MS}) is defined as the difference in the work-functions of the gate material (Φ_M) and the substrate (Φ_S). The work-function difference is dependent on the material of the gate electrode and is weakly dependent on the Fermi level of the substrate.

[0034] The work-function of the gate electrode is a characteristic property of the material itself, and is the amount of energy, usually expressed in electron volts, required to remove an electron from the Fermi level of the material. The work-function of a gate electrode is important for its effect on the threshold voltage for a transistor. For example, there can be over a one-volt difference in the work-function between the gate electrodes of n+ polysilicon and p+ polysilicon.

[0035] Referring now to the drawings, where like elements are designated by like reference numerals, FIG. 4 shows an exemplary pixel cell 400 according to a first exemplary embodiment of the present invention.

[0036] FIG. 4 illustrates an isolation region 409 in a substrate 401. There is also a gate structure 450 of a transfer transistor. The gate 450 includes a first layer of insulating material 453a over the substrate 401, a gate electrode

452 over the first insulating layer 453a, and a second insulating layer 453b over the gate electrode 452. On two lateral opposing sides of the stack of layers 453a, 452, and 453b, are side wall spacers 451.

[0037] Adjacent to the gate 450 is a photo-conversion device, which for exemplary purposes is a pinned photodiode 421. The pinned photodiode 421 has a surface layer 405 of a first conductivity type overlying a region 414 of a second conductivity type within the substrate 401. Also adjacent to the gate 450, but on an opposite side to the pinned photodiode 421, is a sensing node, which, for exemplary purposes, is a floating diffusion region 404.

[0038] In a first exemplary embodiment of the invention, the transfer gate electrode 452 work-function is tailored by forming the transfer gate 450 comprising a layer of doped or undoped mid-gap material. Mid-gap materials are those materials having a work-function falling between the work-functions of p+ silicon (Si) and n+ Si or, otherwise stated, between the conduction band and valence band of Si. Mid-gap materials may be comprised of two or more constituent materials. Examples of such materials include $\text{Si}_{1-x}\text{Ge}_x$, TiN/W, Al/TiN, Ti/TiN, and TaSiN which are commonly used in semiconductor devices. Altering the mole fraction of the constituent material alloys in a mid-gap material alters the work-function of the mid-gap material.

[0039] The work-function of the mid-gap material, and therefore the gate electrode 452, is tailored by altering the mole fractions of the constituent materials, such that the work-function of the gate electrode 452 is higher than the work-function of a conventional n+ gate electrode 8 (FIG. 2). At a same threshold voltage, V_t , the dopant concentration in the channel region 455 of the transfer gate 450 is determined at least in part by the work-function of the gate electrode 452 and is lower than in a conventional pixel cell 10 (FIGS. 1 and 2), or may be eliminated.

[0040] The lower dopant concentration of the channel region serves to reduce a potential barrier in a photodiode/transfer gate region 430 where the transfer gate 450 and the pinned photodiode 421 are in close proximity and to improve the sub-threshold leakage characteristics of the transfer gate 450.

[0041] The formation of the pixel cell 400 shown in FIG. 4 will be described in connection with FIGS. 5A-C below. No particular order is required for any of the actions described herein, except for those logically requiring the results of prior actions. Accordingly, while the actions below are described as being performed in a general order, the order is exemplary only and may be altered.

[0042] FIG. 5A depicts an isolation region 409 in a substrate 401. Preferably, the substrate 401 is a p-type silicon substrate 401. The isolation region 409 is formed within the substrate 401 and is filled with a dielectric material, which may include an oxide, such as SiO or SiO₂; oxynitride; a nitride, such as silicon nitride; silicon carbide; a high temperature polymer; or other suitable material. Preferably, as in this example, the isolation region is a shallow trench isolation (STI) region 409, formed by known STI processes.

[0043] As shown in FIG. 5B, a gate 450 of a transfer transistor is formed over the substrate 401. Preferably, the gate 450 is a multilayer transfer gate stack comprising a first insulating layer 453a of grown or deposited silicon oxide on the substrate 401, a gate electrode 452 comprising a mid-gap material, and a second insulating layer 453b, which may be formed of an oxide (SiO₂), a nitride (silicon nitride), an oxynitride (silicon oxynitride), ON (oxide-nitride), NO (nitride-oxide), or ONO (oxide-nitride-oxide). The first and second insulating layers, 453a and 453b, and the gate electrode 452 may be formed by conventional deposition methods, such as chemical vapor deposition (CVD) or plasma chemical vapor deposition (PECVD), among others. The layers 453a,

452, and 453b are patterned to form the multilayer stack structure shown in FIG. 5B.

[0044] The mid-gap material forming the gate electrode 452 has a work-function falling between the work-functions of p+ Si and n+ Si. The mid-gap material may be, for example $\text{Si}_{1-x}\text{Ge}_x$, TiN/W, Al/TiN, Ti/TiN, TaSiN or any other appropriate material. The mole fractions of the constituent materials are selected to achieve a desired work-function. The work function of the mid-gap material at least in part determines the dopant concentration in a channel region 455 (FIG. 4) of the gate 450, such that at a given threshold voltage, the dopant concentration is reduced or eliminated as compared with a conventional pixel cell 10 (FIGS. 1 and 2).

[0045] Preferably, the mid-gap material for the gate electrode 452 is a layer 452 of $\text{Si}_{1-x}\text{Ge}_x$. The mole fractions of Ge and Si are altered to achieve a desired work-function. Increasing the Ge mole fraction decreases the work-function. Preferably, the mole fraction of Ge in the $\text{Si}_{1-x}\text{Ge}_x$ layer 452 is approximately 0.4.

[0046] Also, the $\text{Si}_{1-x}\text{Ge}_x$ layer 452 may be doped with p-type or n-type dopants. N-type dopants may be phosphorus, arsenic, antimony, or any other appropriate n-type dopant. P-type dopants may be boron, indium, or any other suitable p-type dopant.

[0047] As is the case with n+ and p+ silicon, p+ $\text{Si}_{1-x}\text{Ge}_x$ has a higher work-function than n+ $\text{Si}_{1-x}\text{Ge}_x$. The work-functions of p+ and n+ $\text{Si}_{1-x}\text{Ge}_x$ are discussed in King et al., "Electrical Properties of Heavily Doped Polycrystalline Silicon-Germanium Films," IEEE Trans. Elect. Dev. Vol. 2(41) pp. 228-232 (Feb. 1994), which is incorporated herein by reference. As discussed by King et al. and noted above, the work-function of p+ and n+ $\text{Si}_{1-x}\text{Ge}_x$ decreases as the mole fraction of Ge increases. The mole fraction of Ge in a p+ $\text{Si}_{1-x}\text{Ge}_x$ layer 452, however, has a greater effect on the work-function difference than in an

$n+$ $\text{Si}_{1-x}\text{Ge}_x$ layer 452. Therefore, for a same range of mole fractions of Ge, a $p+$ $\text{Si}_{1-x}\text{Ge}_x$ layer 452 will have a wider range of corresponding work-functions than will an $n+$ $\text{Si}_{1-x}\text{Ge}_x$ layer 452.

[0048] Referring to FIG. 5B, the invention is not limited to the structure of the gate 450 as described above. Additional layers may be added or the gate 450 structure may be altered as is desired and known in the art, provided that the work-function of the gate electrode 452 is tailored according to the invention. For example, a silicide layer (not shown) may be formed between the gate electrode 452 and the second insulating layer 453b. The silicide layer may be included in the gate 450, or in all of the transistor gate structures in an image sensor circuit, and may be titanium silicide, tungsten silicide, cobalt silicide, molybdenum silicide, or tantalum silicide. This additional conductive layer may also be a barrier layer/refractor metal, such as TiN/W or $\text{W}/\text{N}_x/\text{W}$, or it could be formed entirely of WN_x .

[0049] A channel implant may also be conducted to implant a desired dopant in a channel region 455 below where the gate 450 is to be formed. Any suitable known technique may be used to dope channel region 455. Accordingly, channel region 455 may be doped, for example, before or after the gate 450 is fully formed. The channel region 455 may be implanted with a p -type dopant, which may be boron, indium, or any other suitable p -type dopant. As noted above, however, a channel implant may also be eliminated.

[0050] Referring to FIG. 5C, a sensing node 404 is formed adjacent to the gate 450 and on an opposite side of the gate 450 from where the photodiode 421 is to be formed. Preferably, the sensing node 404 is a floating diffusion region 404. The floating diffusion region 404 is formed in the substrate 420 by known methods as a doped region of second conductivity type, which is preferably n -type.

[0051] A photo-conversion device is also formed adjacent to the gate 450 on a side opposite to the floating diffusion region 404. Preferably, as is shown in FIG. 5C, the photo-conversion device is a pinned photodiode 421. The pinned photodiode 421 may be formed by methods known in the art. Accordingly, a photodiode region 414 of a second conductivity type is formed in the substrate 401. Preferably, the photodiode region 414 is a lightly doped n-region 414. The n-region 414 is approximately aligned with an edge of the gate 450 and forms a photosensitive charge accumulating region for collecting photo-generated electrons.

[0052] A doped surface layer 405 of a first conductivity type is formed over the n-region 414. Preferably, the doped surface layer 405 is a highly doped p+ surface layer 405. The active dopant concentration of the p+ surface layer 405 is preferably within the range of approximately 1×10^{18} to 1×10^{19} atoms per cm^3 , and more specifically is approximately 5×10^{18} atoms per cm^3 . Boron is the preferred dopant, but other suitable p-type dopants, such as indium, may be used. Preferably, the p+ surface layer 405 is spaced away from the gate electrode 452 by approximately 800 to 1200 Å.

[0053] To complete the structure shown in FIG. 4, sidewall spacers 451 are formed on the sidewalls of the gate 450 by conventional methods. The sidewall spacers 451 may be an appropriate dielectric material, such as silicon dioxide, silicon nitride, an oxynitride, ON, NO, ONO, or TEOS, among others.

[0054] Further processing may be employed to form other conventional features of a pixel cell.

[0055] A second exemplary embodiment of the invention is described below. The second exemplary embodiment is similar to the first exemplary embodiment described above in connection with FIGS. 4 through 5C, except for the material comprising the gate electrode 452. For simplicity, the second exemplary embodiment is described with reference to FIG. 4 and only the

differences with respect to the gate electrode 452 are noted. Also, the formation of a pixel cell 400 according to the second exemplary embodiment is similar to that described above in connection with FIGS. 5A through 5C, except that the gate electrode 452 is formed of a different material. For simplicity, a description of the process is not repeated and only the differences with respect to the gate electrode 452 are noted.

[0056] According to the second exemplary embodiment of the invention, the work-function of the transfer gate electrode 452 is tailored by altering the dopant type and/or concentration of the gate electrode 452. The gate electrode 452 is a doped layer of polysilicon 452.

[0057] Preferably, the doped layer of polysilicon 452 is a degenerately doped p+ layer 452 having a dopant concentration of greater than or equal to approximately 1×10^{20} atoms per cm^3 . Preferably, the p-type dopant is boron, and the p+ layer 452 is doped using a boron-11 implant, as is known in the art. A p+ gate electrode 452 has a higher work-function than the convention n+ transfer gate electrode 8 of pixel cell 100 (FIG. 2).

[0058] The work function of the p+ gate electrode 452 at least in part determines the dopant concentration in a channel region 455 (FIG. 4) of the gate 450, such that at a given threshold voltage, the dopant concentration is reduced or eliminated as compared a conventional pixel cell 10 (FIGS. 1 and 2). The lower dopant concentration in the channel region of the transfer gate 450 serves to reduce a potential barrier in the photodiode/transfer gate region 430 and to improve the sub-threshold leakage characteristics of the transfer gate 450.

[0059] Alternatively, the doped layer of polysilicon 452 may be a lower doped p-type or n-type polysilicon layer 452. For purposes of this specification, the term "lower doped" refers to a dopant concentration that is below a concentration of a heavily doped p+ or n+ region. Accordingly, lower doped polysilicon has a work-function between that of n+ and p+ polysilicon. At a

given threshold voltage, a gate 450 comprising a lower doped polysilicon gate electrode 452 having a work-function between the work-functions of p+ Si and n+ Si. The work-function of the lower doped polysilicon layer 452, and thus the gate 450 work-function, is tailored by changing the dopant type and concentration. The dependence of work-function on n-type dopant concentrations in a polysilicon gate is discussed by Lifshitz, "Dependence of the Work-Function Difference Between the Polysilicon Gate and Silicon Substrate on the Doping Level in the Polysilicon," IEEE Trans. Elect. Dev. Vol. ED-32(3) pp. 617-621 (Mar. 1985), which is incorporated herein by reference.

[0060] A lower doped n-type gate electrode 452 may be doped with phosphorus, arsenic, antimony, or any other appropriate n-type dopant. Preferably, however, the lower doped gate electrode 452 is a p-type gate electrode 452 and a p-type dopant is used, such as boron, indium, or any other suitable p-type dopant.

[0061] The lower doped gate electrode 452 may be formed using conventional techniques. For example, a dopant resulting in poor activation, such as indium, may be used. Also, a polysilicon layer 452 that is of one conductivity type may be subsequently counter doped with a dopant of a different conductivity type to achieve the desired active dopant concentration.

[0062] The work function of the lower doped gate electrode 452 at least in part determines the dopant concentration in a channel region 455 (FIG. 4) of the gate 450, such that at a given threshold voltage, the dopant concentration is reduced or eliminated as compared with a conventional pixel cell 10 (FIGS. 1 and 2). The reduced dopant concentration in the channel region 455 serves to reduce a potential barrier in the photodiode/transfer gate region 430 and improve charge transfer from the photodiode 421 to the floating diffusion region 404.

[0063] Lowering the active dopant concentration in the polysilicon layer 452 will also lead to depletion of the polysilicon layer 452. Depletion of the polysilicon layer 452 occurs near an interface with the oxide layer 453a which separates the polysilicon layer 452 from the substrate 401. The thickness of the depletion region plus the thickness of the oxide layer 453a yields an increased thickness in the total effective oxide layer.

[0064] In additional exemplary embodiments of the invention, a pixel cell may have a gate structure that includes two or more regions having differently tailored work-functions. Two such exemplary embodiments are described below in connection with FIGS. 6A-7B. A gate structure having a plurality of gate regions may be generally formed as described above in connection with FIGS. 5A-5C, except that operations can be performed separately on each region. Additionally, the gate structure's channel region can also be differently doped under each gate region.

[0065] The gate regions may be formed of different materials, or a same material that is doped to create regions having different work-functions. For example, one gate region may be formed of $\text{Si}_{1-x}\text{Ge}_x$ and another may be formed of p+ polysilicon; or one gate region may be formed of p+ $\text{Si}_{1-x}\text{Ge}_x$ and another one gate electrode may be formed of n+ $\text{Si}_{1-x}\text{Ge}_x$. It should also be noted that one or more of the gate regions may be formed of n+ polysilicon. Additionally, the channel region may have different dopant concentrations under each gate region.

[0066] FIG. 6A depicts a top plan view of a portion of a pixel cell 600 having a gate, which is illustratively a transfer gate 650, that comprises two gate regions 650a and 650b with differently tailored work-functions. FIG. 6B depicts a cross sectional view of the pixel cell 600 along line 6B-6B'. In the example of FIGS. 6A and 6B, transfer gate region 650b has a higher work-function than

gate region 650b, but gate region 650a may instead have a higher work-function.

[0067] Referring to FIG. 6A, the transfer gate 650 is between a photo-conversion device, which is shown as photodiode 621, and a sensing node, which is shown as floating diffusion region 604. There are isolation regions, which are shown as STI regions 609, on opposing sides of photodiode 621 and floating diffusion region 604 and partially underlying portions of transfer gate 650. The STI regions 609 define between them an electrically active area, which, in the example of FIGS. 6A and 6B, includes the photodiode 621, the floating diffusion region 604, and the channel regions 655a, 655b (FIG. 6B).

[0068] As shown in FIG. 6B, the gate 650 has a gate oxide layer 653a over the substrate 601 and between the STI regions 609. Conductive regions, 652a and 652b are over the gate oxide layer 653a. Conductive region 652a has a lower work-function than region 652b. Accordingly, region 652a may be formed of a different material than region 652b. Also, regions 652a and 652b may be a same material with different doping characteristics to achieve different work-functions. For purposes of this specification, the term “doping characteristics” refers to the dopant used, conductivity type, and dopant concentration. Any one of, or any combination of, doping characteristics may be used to achieve different work-functions. Conductive region 652a may be an n+ polysilicon gate electrode, and region 652b may have a work-function greater than that of n+ polysilicon. Also, both regions 652a and 652b may have work-functions greater than that of n+ polysilicon. There is also an insulating layer 653b over the regions 652a and 652b.

[0069] Channel regions 655a and 655b are below and correspond to the gate regions 650a and 650b, respectively. Channel regions 655a and 655b may have same or different dopant concentrations. For example, if a same

threshold voltage is desired for both gate regions 650a and 650b, channel region 655b may have a lower dopant concentration than channel region 655a.

[0070] As shown in FIGS. 6A and 6B, gate region 650a extends beyond STI 609 and over the active area by a distance D_a . Similarly, gate region 650b extends beyond STI 609 and over the active area by a distance D_b . Distances D_a and D_b may be equal to or different from one another.

[0071] The different work-functions, different channel dopant concentrations, and/or different distances, D_a and D_b , for gate regions 650a and 650b may be used to modulate and optimize the transfer gate and its operation as desired.

[0072] FIG. 7A depicts a top plan view of a portion of a pixel cell 700 having a gate, which is illustratively a transfer gate 750, comprising three gate regions: 750a, 750b, and 750c. FIG. 7B depicts a cross sectional view of the pixel cell 700 along line 7B-7B'. The transfer gate regions 750b and 750c have higher work-functions than gate region 750a.

[0073] Referring to FIG. 7A, transfer gate 750 is between a photo-conversion device, which is illustrated as photodiode 721, and a sensing node, which is shown as floating diffusion region 704. There are isolation regions, which are illustratively STI regions 709, on opposing sides of photodiode 721 and floating diffusion region 704 and partially underlying portions of transfer gate 750. The STI regions 709 define between them an electrically active area, which, in the example of FIGS. 7A-7B, includes the photodiode 721, the floating diffusion region 704, and the channel regions 755a, 755b, 755c (FIG. 7B).

[0074] As shown in FIG. 7B, the gate 750 has a gate oxide layer 753a over a substrate 701 and between the STI regions 709. Conductive regions, 752a, 752b, and 752c are over the gate oxide layer 753a. Conductive region

752a has a lower work-function than regions 752b and 752c. Conductive regions 752b and 752c may have same or different work-functions. Accordingly, any appropriate combination of materials and/or doping characteristics may be used to achieve the desired work-functions for the regions 752a, 752b, and 752c. Conductive region 752a may be formed of n+ polysilicon, and regions 752b and 752c may have work-functions greater than that of n+ polysilicon. Also, regions 752a, 752b, and 752c may have work-functions greater than that of n+ polysilicon. There is also an insulating layer 753b over the regions 752a, 752b, and 752c.

[0075] Channel regions 755a, 755b, and 755c correspond to the gate regions 750a, 750b, and 750c, respectively. Channel region 755a has a higher dopant concentration than channel regions 755b and 755c. Channel regions 755b and 755c may have same or different dopant concentrations.

[0076] Gate regions 750b and 750c overlie the areas where photodiode 721 meets STI region 709. The area where the photodiode 721 and STI region 709 meet is typically a high leakage region due to STI stress related issues. Providing gate regions 750b and 750c having higher work-functions and reducing the dopant concentration in the channel regions 755b and 755c may control the sub-threshold leakage for the transfer transistor.

[0077] Although additional embodiments in FIGS. 6A-7B show a transfer gate device having two or three gate regions having specific configurations, the invention is not limited to specific numbers or configurations. Accordingly, a gate may also have more than three gate regions and the gate regions may have other configurations.

[0078] In any of the embodiments described above, a gate may be part of a PMOS transistor, rather than an NMOS transistor described in connection with FIGS. 4-7B above. If the gate is part of a PMOS transistor, the photodiode would be an npn-type photodiode instead of a pnp-type photodiode as described

in connection with FIGS. 4-7B above, and the conductivity types of other structures would change accordingly.

[0079] While the above embodiments discuss a transfer gate, other transistor gates in a pixel cell according to the invention may be formed similarly to the transfer gate as described above in connection with FIGS. 4-7B.

[0080] Turning to FIG. 8, a schematic diagram of a pixel cell 800 is depicted according to an exemplary embodiment of the invention. The pixel cell 800 has a floating diffusion node 804 and a pinned photodiode 821, which are formed as described above in connection with FIG. 5C. There is also a transfer transistor 850 having a gate formed according to one of the embodiments described above in connection with FIGS. 4-7B.

[0081] The pixel cell 800 also comprises a source follower transistor 870, a reset transistor 860, and a row select transistor 880. Each of the transistors 860, 870, and 880 comprise at least one gate region. At least one of the reset 860 and source follower 870 transistors may have a gate formed as described above in connection with FIGS. 4-7B. The transfer 850, reset 860, and source follower 870 gates may be formed having identically tailored work-functions; or one or more of the transfer 850, reset 860, and source follower 870 gate regions may be formed having a work-function tailored differently from the others.

[0082] The work-functions of the reset 860 and source follower 870 gates may determine in part a dopant concentration in a channel region of the reset 860 and source follower 870 transistors, respectively. Alternatively, a dopant concentration in a channel region of the reset 860 and source follower 870 transistors may be a conventional dopant concentration, and the work-functions of the reset 860 and source follower 870 gates may determine a desired threshold voltage for the reset 800 and source follower 870 transistors.

[0083] In any of the embodiments described herein, where both n-type and p-type gates are desired for a single pixel cell, the transfer gate 850 and other gates formed as part of the pixel cell may be formed by a dual polysilicon process in which separate mask levels are used to form the n-type and p-type gates as known in the art.

[0084] Although the invention is described in connection with a four-transistor (4T) pixel cell, the invention may also be incorporated into other CMOS pixel cell designs having different numbers of transistors. Without being limiting, such a design may include a three-transistor (3T) cell or a five-transistor (5T) cell. A 3T cell omits the transfer transistor, but may have a reset transistor adjacent to a photodiode. A 5T cell differs from the 4T cell by the addition of a transistor, such as a shutter transistor or a CMOS photogate transistor.

[0085] Depending on the design of a pixel cell, a transfer gate may not be adjacent to a photo-conversion device. In such as case, embodiments of the invention described herein with respect to a transfer transistor may instead be applicable to a different transistor. Without being limiting, such a transistor may be, for example, a reset transistor.

[0086] FIG. 9 is a block diagram of an exemplary CMOS image sensor 999 according to an embodiment of the invention. The imaging device has a pixel array 990 containing a plurality of pixel cells arranged in rows and columns. One or more of the pixel cells in the array 990 is a pixel cell 800 as described above in connection with FIG. 8.

[0087] The image sensor 999 operates as is known in the art. Accordingly, the pixels of each row in array 990 are all turned on at the same time by a row select line, and the pixels of each column are selectively output by respective column select lines. The row lines are selectively activated by a row driver 991 in response to row address decoder 992. The column select lines are selectively activated by a column driver 965 in response to column address

decoder 971. The pixel array is operated by the timing and control circuit 995, which controls address decoders 992, 971 for selecting the appropriate row and column lines for pixel signal readout. The pixel column signals, which typically include a pixel reset signal (V_{rst}) and a pixel image signal (V_{sig}), are read by a sample and hold circuit (S/H) 961 associated with the column driver 965. A differential signal ($V_{rst} - V_{sig}$) is produced by differential amplifier (AMP) 962 for each pixel which is amplified and digitized by analog to digital converter (ADC) 975. The analog to digital converter 975 supplies the digitized pixel signals to an image processor 985 which forms a digital image.

[0088] Although the invention is described in connection with a CMOS image sensor, the invention is also applicable to analogous structures of a charge coupled device (CCD) image sensor.

[0089] A typical processor-based system 1010, which includes the CMOS image sensor device 999 above, is illustrated generally in FIG. 10. A processor-based system 1010 is exemplary of a system having digital circuits that could include CMOS image sensor devices. Without being limiting, such a system could include a computer system, camera system, scanner, machine vision, vehicle navigation, video phone, surveillance system, auto focus system, star tracker system, motion detection system, image stabilization system, and data compression system.

[0090] A processor-based system, for example a computer system, generally comprises a central processing unit (CPU) 1044, such as a microprocessor, that communicates with an input/output (I/O) device 1046 over a bus 1052. The CMOS image sensor 999, which produces an image output from a pixel array, also communicates with the CPU 1044 over bus 1052. The processor-based system 1010 also includes random access memory (RAM) 1048, and may include peripheral devices, such as a floppy disk drive 1054 and a compact disk (CD) ROM drive 1056, which also communicate with CPU 1044

over the bus 1052. The CMOS image sensor 999 may be combined with a processor, such as a CPU, digital signal processor, or microprocessor, with or without memory storage on a single integrated circuit or on a different chip than the processor.

[0091] While the invention has been described in detail in connection with preferred embodiments known at the time, it should be readily understood that the invention is not limited to the disclosed embodiments. Rather, the invention can be modified to incorporate any number of variations, alterations, substitutions or equivalent arrangements not heretofore described, but which are commensurate with the spirit and scope of the invention.
